

# Facility Location with Nonuniform Hard Capacities

Martin Pál   Éva Tardos   Tom Wexler  
Cornell University

# Metric Facility Location

$F$  is a set of facilities.

$D$  is a set of clients.

$c_{ij}$  is the distance between any  $i$  and  $j$  in  $D \cup F$ .

Facility  $i$  in  $F$  has cost  $f_i$ .

# Problem Statement

We need to:

- 1) Pick a set  $S$  of facilities to open.
- 2) Assign every client to an open facility (a facility in  $S$ ).

**Goal:** Minimize cost of  $S$  + distances.

# More Formally

Facility cost  $c_f(S)$ : sum of  $f_i$  over all  $i$  in  $S$ .

Service cost  $c_s(S)$ : sum of distances from clients to assigned facilities.

Goal: Minimize  $c_f(S) + c_s(S)$ .

# Hard Capacities

Every facility  $i$  has a capacity  $u_i$ .  
(how many clients  $i$  can serve)

**Soft Capacities:** can open  $k$  copies of facility  $i$  and serve  $k \cdot u_i$  clients.

**Hard Capacities:** can't open multiple copies of any facility.

**Note:** with hard capacities, there may be no solution.

# Previous Results I

## Techniques Used for Fac. Loc.:

LP rounding

Primal-dual algorithms

Chudak & Shmoys '99, Jain & Vazirani '99:

LP techniques give  $c$ -approx. for  
**soft capacities.**

**Problem:** Known LPs have large  
integrality gap for **hard capacities.**

# Previous Results II

## Techniques Used for Fac. Loc.:

Local search

Korupolu et al '98, Chudak & Williamson '99:

Local search gives  $c$ -approx. for  
uniform, hard capacities.

Arya et al '01:

Local search gives  $c$ -approx. for  
nonuniform, soft capacities.

Our Result:

Local search gives  $c$ -approx. for  
nonuniform, hard capacities.

# Local Search

- 1) Start with any feasible solution.
- 2) Improve solution with "local operations".
- 3) Stop when there are no remaining operations that lower the cost.

Well, almost...

...we want to finish in poly-time:

Each operation is required to lower cost by a factor of  $1/\text{poly}(n,\epsilon)$ .

# Operation 1 (of 3): add

1)  $\text{add}(s)$  - Open facility  $s$ .

If our solution opened  $S$  before,  
 $\text{add}(s)$  means we open  $S \cup \{s\}$  now.

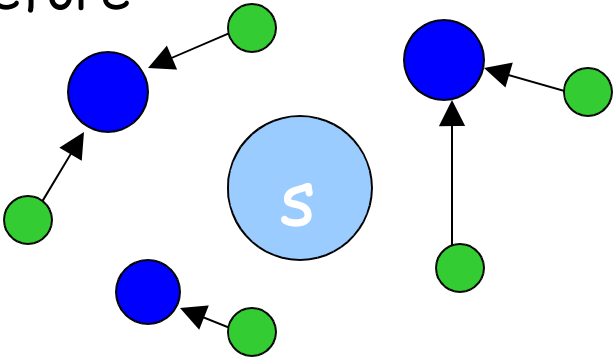

*Given  $S$ , where do we send clients?*

- i Without capacities, we just assign clients the the nearest open facility.
- i With capacities, we can still get optimum by solving a min cost flow.

# Operation 2: open

2)  $\text{open}(s, T)$  - Open facility  $s$ , send clients from  $T$  to  $s$ , and close  $T$ .

before

If we close  $t$ , we are only allowed to send  $t$ 's clients to  $s$ .

after

Capacity of  $s$   
 $\geq$   
# of clients  
served by  $T$ .

# Operation 3: close

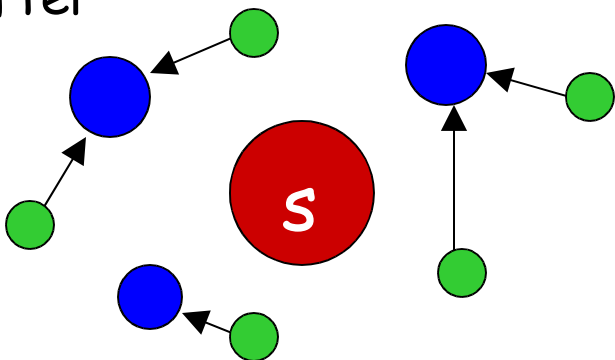

3)  $\text{close}(s, T)$  - Open facilities  $T$ , send clients from  $s$  to  $T$ , close  $s$ .

before

Capacity of  $T$   
 $\geq$   
# of clients  
served by  $s$ .

after

# Can We Find Operations?

Too many operations like  $\text{open}(s, T)$  and  $\text{close}(s, T)$  to consider all!

Can we get find the best one?

Not quite, but close enough.

**Plan:** For each facility  $s$ , generate a good set  $T$  for the  $\text{open}$  operation.

Likewise for  $\text{close}$ .

# Good Operations

Want to open  $s$ , need to pick  $T$ .

**Idea:**  $+$  has demand & benefit.

A knapsack problem! (have scheme)

$\text{Value}(t) = f_t + \text{reassignment costs.}$

$\text{Size}(t) = \# \text{ clients assigned to } t.$

$$\text{max. } \sum_{t \in T} \text{Value}(t)$$

$$\text{s. t. } \sum_{t \in T} \text{Size}(t) \leq \text{cap.}(s).$$

# Service Cost

What can we say about the output of our algorithm?

**Thm:** [Korupolu et al]

If no **add(s)** op. improves solution  $S$ ,

$$c_s(S) \leq c_s(S^{\text{OPT}}) + c_f(S^{\text{OPT}}).$$

So service cost is low. What about facility cost?

# Facility Cost

Bounding  $c_f(S)$ :

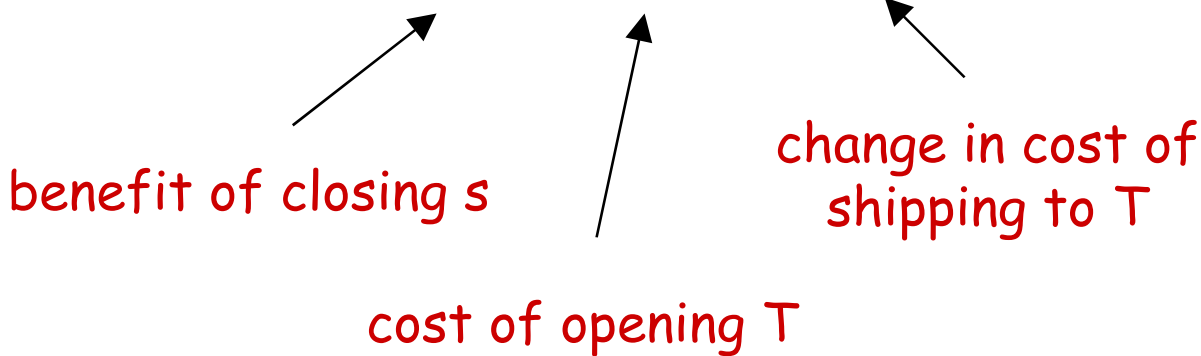

Local opt.  $\Rightarrow 0 \leq$  operation costs.  
(for any operation)

Every operation gives a bound:

Consider  $\text{close}(s, T)$ .

$$c_f(s) \leq c_f(T) + \Delta$$

benefit of closing  $s$

cost of opening  $T$

change in cost of shipping to  $T$

# The Plan

**Idea:** Pick some set of operations.

Each gives  $c_f(T) \leq c_f(T') + \Delta$  for some sets  $T$  and  $T'$ .

(closed)

(opened)

Pick operations so that

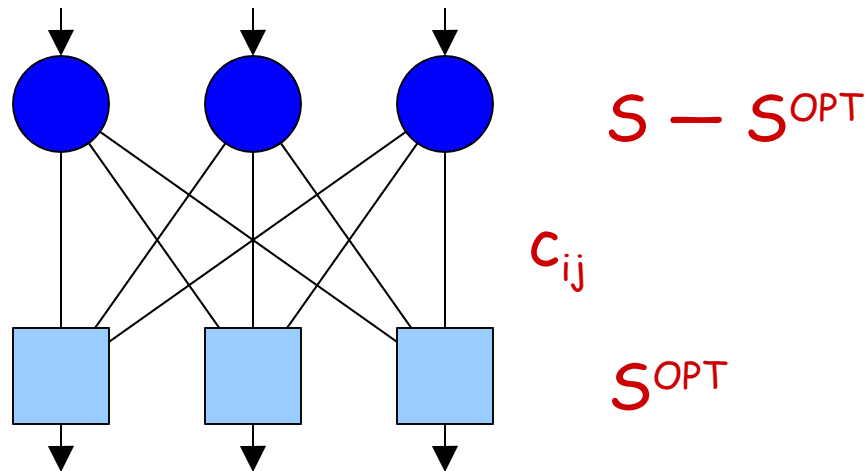

- each  $s$  in  $S$  is closed exactly once.
- each  $s$  in  $S^{\text{OPT}}$  is opened  $\leq k$  times.
- reassignment costs are small.

# The Exchange Graph

Operations should depend on  $S^{\text{OPT}}$ .

Flow in = demand served by  $S$

Flow out  $\leq$  capacity of facilities in  $S^{\text{OPT}}$

We want:  $\text{swap}(S^{\text{OPT}}, S - S^{\text{OPT}})$ .

We don't have such an operation.

# Looking For Operations

Flow in = demand served by  $S$

Flow out  $\leq$  capacity of facilities

$y$  = flow of clients from  $S$  to  $S^{OPT}$ .

$$\text{cost}(y) \leq c_s(S) + c_s(S^{OPT})$$

Cost of  $\text{swap}(S^{OPT}, S - S^{OPT}) \leq$

$$\text{cost}(y) + c_f(S^{OPT}) - c_f(S).$$

# What is the Flow?

Conveniently, the flow is a tree!

(or rather a forest... just augment cycles)

How do we get operations from this?

Remember, we will use inequalities like

$$c_f(T) \leq c_f(T') + \Delta.$$

Since flow is cheap,  $\Delta$  is small.

# First Attempt

Just use  $\text{close}(s, T)$ , picking  $T$  to be the neighbors of  $s$  in the tree.

**Problem:** Expensive facilities in  $S^{\text{OPT}}$  may be opened many times.

# Instead...

Consider subtrees of depth 2.

Each  node needs to be closed.

Partition these nodes into 3 sets.  
We'll handle each set separately.

# Heavy Nodes

Heavy Nodes: ● nodes responsible for  $> \frac{1}{2}$  the clients sent to r

Note: There can be only one.

Only 1, so close it & open neighbors.  
(i.e. use the naive approach)

# Light Dominating

Light Dominating: ● nodes that send  $\geq \frac{1}{2}$  their clients up to  $\square_r$

Worst case, this doubles  $\square_r$ 's capacity: Split into a few operations.

# Last Case

Light Nondominating: ● nodes that send  $\geq \frac{1}{2}$  their clients down.

Order these by # of clients sent up.

To close facility  $i$  open:  $C(i), C(i+1)$

# Last Case

Light Nondominating: ● nodes that send  $\geq \frac{1}{2}$  their clients down.

Order these by # of clients sent up.

To close facility  $i$  in LN, open:

The children of  $i$

The children of  $i+1$

# Last Case (cont')

For the last LN node, we open the root instead.

For LN in total,  $r$  is opened once, and the bottom facilities are opened at most twice.

# In Total

For each subtree,

$r$  is opened at most 4 times,

$s$  are opened at most 2 times.

Every facility in  $S^{OPT}$  is a root of 1 subtree and a child in 1 subtree.

Altogether

i Every node in  $S$  is closed

ii Every node in  $S^{OPT}$  is opened at most 6 times.

# Result

**Thm:** Our local search algorithm gives a **9-approx.** for facility location with hard, nonuniform capacities.

**Note 1:** Actually a  $(9 + \epsilon)$ -approx.

**Note 2:** Scaling lowers it to 8.53...

**Note 3:** At best, algorithm is a 4-approx.

# LP Integrality Gap

Why not use LPs for this problem?

The LP solution fully opens the **green** facility and opens 1/100th of the **red** facility, thus paying a facility cost of 2.

Any integer solution pays 100.

# Lower Bound

How much better might our alg. be?

Thm: Alg. is at best a 4-approx.

# The close( $s$ , $T$ ) Operation

Knapsack?  $\text{value}(t)$  isn't well defined:  
Which clients should  $t$  serve?

Solution: Use  $\Delta \neq$  to get an upper estimate for rerouting cost.

To send demand to  $t$ , first ship it to  $s$ , then to  $t$ .

Now  $\text{value}(t) = \text{cap.}(t) * \text{dist.}(s, t)$   
 $\text{size}(t) = \text{cap.}(t)$

(now we have a covering knapsack problem)
